The energy of a pointlike vortex is calculated for a layered superconductor with very weak interlayer Josephson coupling. An energy barrier existing near the sample surface is found. Magnetization relaxation due to thermally activated penetration of pointlike vortices is considered. An initial avalanche-type decay of magnetization is predicted.

I. INTRODUCTION

Magnetization relaxation measurements are an effective method to investigate the flux dynamics phenomena, current-voltage characteristics, and critical current in superconductors. In type-II superconductors magnetization relaxation is determined by the vortices penetration, flow, and pinning. The flux penetration process begins when the external magnetic field \( H \) becomes higher than a certain edge field \( H^* \). In the case of a cylinder subjected to a parallel field the value of \( H^* \) is bigger than the lower critical field \( H_{c1} \) and smaller than the thermodynamical critical field \( H_c \). The difference between \( H^* \) and \( H_{c1} \) depends on the interaction of the vortices with the pinning centers and the sample surface. In continuous superconductors the attraction of the Abrikosov vortices to the sample surface results in the Bean-Livingston barrier. This barrier prevents penetration of the Abrikosov vortices inside the sample. The value of \( H^* \) determined by the Bean-Livingston barrier depends on the roughness of the surface. It is maximal in the case of an ideal flat surface. In the absence of the pinning centers in the bulk the edge field \( H^* \) is equal to the thermodynamical critical field \( H_c \).

Logarithmic relaxation of the magnetization \( M \) is one of the main results of the well-known Anderson flux-creep model. A nonlogarithmic magnetization relaxation was considered in the vortex-glass and collective creep (pinning) (Ref. 8) models. A considerable deviation from the logarithmic relaxation law is observed in a lot of experimental studies for the high-temperature superconductors. In particular, a pronounced maximum on the curve of the magnetization relaxation rate is found in Ref. 11. Experimental study presented the evidence that the Bean-Livingston barrier is the origin of the irreversibility observed in high-quality YBa\(_2\)Cu\(_3\)O\(_7\) single crystals near the critical temperature \( T_c \). It is emphasized in Ref. 15 that the Bean-Livingston barrier is especially effective for the high-temperature superconductors. A crossover from the bulk pinning to the surface pinning is observed and discussed in detail in Ref. 16. The considerable deviation from the logarithmic decay of the magnetization is one of the consequences of the specific quasi-two-dimensional nature of superconductivity in the high-temperature superconductors.

The most prominent high-temperature superconductors and, in particular, the Bi- and Tl-based compounds, consist of a periodic stack of the two-dimensional CuO layers (ab planes) where the superconductivity presumably resides. These materials are extremely anisotropic and, in particular, the density of the superconducting current in the direction perpendicular to the layers (c direction) is much less than in the ab planes. The discovery of the layered anisotropic high-\( T_c \) superconductors stimulated many theoretical studies of layered superconductors with weak interlayer Josephson coupling. In particular, the specific pointlike (or pancake) vortices were introduced and investigated. Each of these pointlike vortices is residing only in one of the superconducting layers. The self-energy of an isolated pointlike vortex is proportional to \( \ln(L/\xi) \), where \( L \) is the characteristic size of the sample in the ab plane and \( \xi=\xi_{ab} \) is the coherence length in the ab plane. Thus, the self-energy of an isolated pointlike vortex diverges when \( L/\xi \rightarrow \infty \) and it cannot exist in the bulk of a macroscopic sample.

Interaction of a pointlike vortex with the sample surface as well as for the Abrikosov vortex consists of repulsion and attraction. The repulsion results from the interaction with the Meissner screening current. The attraction results from the increase of the superconducting current density of the pointlike vortex caused by the sample surface. The correlation between these two interactions is determined by the external magnetic field \( H \). At a certain value of \( H=H_1 \) the competition of attraction and repulsion can lead to a stable state localized near the sample surface. The existence of this stable state affects the flux penetration process and, in particular, the magnetization relaxation.

In this paper we study the process of the pointlike vortices penetration into a layered superconductor. We show that this process results in a specific thermally ac-
tivated mechanism of magnetization relaxation, if the external magnetic field $H$ is from the interval $H_{c1} < H < H^*$. We use for calculations the Lawrence-Doniach model in the limit of very weak interlayer Josephson coupling. We consider the case characteristic for the extremely anisotropic high-temperature superconductors, i.e., $\xi << \lambda$, $d << \lambda$, $\xi_c << d$, where $\lambda = \lambda_{ab}$ is the London penetration depth in the $ab$ plane, $d$ is the distance between the layers, and $\xi_c$ is the coherence length in the $c$ direction.

We consider here, as an illustration, the magnetization relaxation for the following problem. A semi-infinite layered superconductor is cooled down to a certain temperature $T$ below the critical temperature in a zero magnetic field. Then, a magnetic field $H$ parallel to the sample surface and perpendicular to the superconducting layers is instantaneously turned on and kept constant. In this case the outline of the scenario of thermally activated magnetization relaxation is as follows. The energy of a single pointlike vortex $G_v$ has a minimum $G_m$, which is detached by an energy barrier $G_g$ from the surface. When the external magnetic field $H$ exceeds a certain value $H_1 = H_{c1}$, the minimum energy $G_m$ becomes negative. It results in a thermally activated penetration of the pointlike vortices inside the sample, where they reside in the vicinity of the energy minimum. The rate of the pointlike vortices penetration inside the sample depends exponentially on the ratio of $G_g / k_BT$, where $k_B$ is the Boltzmann constant. The contribution of the pointlike vortices to the magnetization $\delta M$ is proportional to the number of them and leads to the decay of the magnetization. The interaction of the incoming pointlike vortex with the pointlike vortices residing in the sample affects the value of $G_g$. The shift of the energy barrier $\delta G_g$ due to this interaction is negative and proportional to the number of the pointlike vortices in the sample. As a result, the magnetization relaxation rate increases with the decrease of the magnetization and it leads to the avalanche-type initial magnetization relaxation.

The paper is organized according to the outline of the scenario of thermally activated magnetization relaxation. In Sec. II, we calculate the energy of a single pointlike vortex $G_v$ near the surface of a semi-infinite layered superconductor. In Sec. III, we consider the contribution $\delta M$ to the magnetization resulting from the pointlike vortices residing in the vicinity of the energy minimum $G_m$. In Sec. IV, we study the diffusion of the pointlike vortices nucleating near the sample surface and we calculate the thermally activated flow of these vortices inside the bulk. In Sec. V, we consider the dependence of the shift of the energy barrier $\delta G_g$ on the density of the pointlike vortices residing in the sample. In Sec. VI, we combine the results obtained in the previous sections, derive and solve the magnetization relaxation equation. In Sec. VII, we summarize the overall conclusions.

II. POINTLIKE VORTEX ENERGY NEAR THE SAMPLE SURFACE

We calculate first the energy $G_v$ of a single pointlike vortex residing in one of the superconducting layers near the sample surface. We use for calculations the Lawrence-Doniach model in the limit of very weak interlayer Josephson coupling, i.e., we neglect the superconducting current in the $c$ direction. In this case, the superconducting layers are coupled only electromagnetically via the magnetic field existing between the layers. This approach is valid, when the space scale of the phenomena under consideration is less than the Josephson length $\lambda_j = d \xi_{ab} / \xi_c$. We take into account only the electromagnetic coupling between the superconducting layers. It means that the space scale of the phenomena under consideration is determined by the penetration depth $\lambda$. Thus we assume that $\lambda<\lambda_j$. This assumption is valid, for example, for the Bi- and Ti-based high-temperature superconductors.

Consider a semi-infinite layered superconductor subjected to a magnetic field $H$ parallel to the surface and perpendicular to the layers. Suppose that the $z$ axis is parallel to $H$ and the $x$ axis is perpendicular to the surface. The free-energy functional $F$ for an infinite set of electromagnetically coupled parallel superconducting layers then has the form:

$$F = \frac{d}{2\pi} \left[ \frac{\Phi_0}{4 \pi \lambda} \right]^2 \sum_n \int d^2r \left[ \nabla \phi_n - \frac{2e}{c} A \right]^2 + \frac{1}{8 \pi} \int d^2r (H - B)^2,$$  \hspace{1cm} (2.1)

where $n$ is the number of the layer, $\phi_n$ is the phase of the order parameter in the $n$th layer, $A = (A_x, A_y)$ is the vector potential, $B = \nabla \times A$ is the magnetic field, and $\nabla = (\nabla_x, \nabla_y)$ is the gradient in the layers plane.

Variation of Eq. (2.1) with respect to the vector potential $A$ results in the generalized London equation. Inside the superconductor it has the following form:

$$\nabla^2 A = \frac{d}{\lambda^2} \sum_n \delta(z - nd) \left[ A - \frac{\Phi_0}{2\pi} \nabla \phi_n \right].$$  \hspace{1cm} (2.2)

Solving Eq. (2.2) we can find the magnetic field $B$ and energy $G$ for any configuration of vortices residing in the sample.

Let us now consider a single pointlike vortex near the sample surface. In this case the magnetic field $B(r)$ may be written as

$$B(r) = H \exp \left[ - \frac{x}{\lambda} \right] + b(r).$$  \hspace{1cm} (2.3)

Here the first term represents the magnetic field penetration into the sample in the absence of vortices. The decay of this field is due to the Meissner screening current. The magnetic field $b(r)$ results from the pointlike vortex, and can be calculated by means of Eq. (2.2) and the method of images. It means that, to the pointlike vortex located at $(x,y)$, we add an image pointlike antivortex located at $(-x,y)$ and take for $b(r)$ the sum of the field induced by the vortex and antivortex. The field $b(r)$ automatically vanishes on the sample surface and the boundary condition $B(0,y,z) = H$ is satisfied. Using Eqs. (2.1)–(2.3) we calculate the energy of a single pointlike vortex. Finally,
the dependence of \( G_s \) on \( x \) has the form

\[
G_s = \left( \frac{\Phi_0}{4\pi\lambda} \right)^2 d \ln \left( \frac{2x}{\xi} \right) + \frac{\Phi_0}{4\pi H_d} \exp \left( -\frac{x}{\lambda} \right) - 1 ,
\]

\( x \geq \xi \) . \hspace{1cm} (2.4)

The first term in Eq. (2.4) represents the attraction between the pointlike vortex and its image. It is minimal near the surface and increases monotonically with increase of \( x \). The second term in Eq. (2.4) represents the repulsion of the pointlike vortex from the surface due to the external magnetic field and the associated screening current. It is maximal at \( x = 0 \) and decreases monotonically with the increase of \( x \). The dependence \( G_s(x) \) is shown in Fig. 1 for different values of the magnetic field \( H \). The function \( G_s(x) \) increases monotonically if \( H < H_0 \), where

\[
H_0 = e^{-1} \frac{\Phi_0}{4\pi\lambda^2} .
\]

(2.5)

For \( H > H_0 \) the curve \( G_s(x) \) has a maximum \( G_s \) at \( x = x_g \) and a minimum \( G_m \) at \( x = x_m \). The explicit formulas for \( G_s, x_g, G_m, \) and \( x_m \) can be derived by means of Eq. (2.4) in the case when \( H > H_0 \) and \( \ln(\lambda/\xi) \gg 1 \):

\[
G_s \approx \left( \frac{\Phi_0}{4\pi\lambda} \right)^2 \lambda \xi H ,
\]

\( x_g \approx \frac{\Phi_0}{4\pi\lambda} \frac{1}{\xi} \), \hspace{1cm} (2.6)

\[
G_m \approx \left( \frac{\Phi_0}{4\pi\lambda} \right)^2 \ln \left( \frac{2e^2}{\xi} \ln \left( \frac{4\pi\lambda^2}{\Phi_0} \right) \right) - \frac{\Phi_0}{4\pi} dH ,
\]

\( x_m \approx \lambda \ln \left( \frac{4\pi\lambda^2}{\Phi_0} \right) \), \hspace{1cm} (2.7)

(2.8)

It follows from Eq. (2.8) that the value of the minimum energy \( G_m \) becomes negative when \( H > H_1 \), where

\[
H_1 \approx \frac{\Phi_0}{4\pi\lambda^2} \ln \left( \frac{2e^2}{\xi} \ln \left( \frac{\lambda}{\xi} \right) \right) .
\]

(2.9)

Note that the magnetic field \( H_1 \) is of the same order, but higher than the lower critical field \( H_{c1} \).

Let us estimate the characteristic value of \( G_s \). To do it we use the data obtained for a monocrystal \( \text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_8 \): \( \lambda \approx 3 \times 10^{-5} \text{ cm, } \xi = \xi_{ab} \approx 1.5 \times 10^{-7} \text{ cm} \), \( d \approx 1.5 \times 10^{-7} \text{ cm} \). Using Eq. (2.6) we find that, for \( T \ll T_c \), the value of \( H_1 \) is equal to \( H_1 = 0.013 \text{ T, and} \)

\[
\frac{G_s}{k_B T} = \frac{300}{T} \ln \left( \frac{0.7}{H} \right) ,
\]

(2.11)

where the temperature is given in K, and the magnetic field \( H \) is given in T. It follows from Eq. (2.11) that for \( T \ll T_c \) the energy barrier \( G_s \) is much higher than \( k_B T \).

Thus, if the magnetic field \( H > H_1 \), the minimum energy of the pointlike vortex \( G_m \) is negative, and the energy barrier \( G_s \) is finite. At nonzero temperature it results in the thermally activated penetration of the pointlike vortices into the sample. This mechanism of magnetization relaxation is a new mechanism which is specific for the layered superconductors.

The pointlike vortices penetrated into the sample reside in the vicinity of the energy minimum. The presence of these vortices affects the magnetization leading to its decay.

III. MAGNETIZATION RESULTING FROM POINTLIKE VORTICES

We now calculate the magnetization \( \delta M \) resulting from the pointlike vortices residing in the superconducting layers in the vicinity of the plane \( x = x_m \), i.e., in the vicinity of the energy minimum \( G_m \). These pointlike vortices induce the surface current \( I \), which is the same in each of the layers. The magnetization \( \delta M \) is then given by the formula

\[
\delta M = \frac{I}{cd} .
\]

(3.1)

We calculate the surface current \( I \) in order to find \( \delta M \). To do it, let us suppose that in the \( n \)th superconducting layer the pointlike vortices reside on the line \( x = x_m \), \( z = nd \) with the average linear density \( N \). Note that the value of \( N \) is the same for each of the layers. We denote the \( y \) coordinate of the \( k \)th pointlike vortex residing in the \( n \)th layer as

\[
y_{kn} = k l + u_{kn} .
\]

(3.2)

Here \( l = N^{-1} \) is the average distance between the pointlike vortices in the layers plane. We suppose that the values \( u_{kn} \) are distributed randomly with the distribution function \( f(u) \) and

\[
\int f(u) du = 1 , \quad \int u f(u) du = 0 , \quad \int u^2 f(u) du \approx l^2 .
\]

(3.3)

We use the formula for the Lorentz force \( F_L \) acting on a pointlike vortex to derive the expression for the surface current \( I \). As the value of \( I \) is the same in each of the layers, we calculate \( I \) for the layer with the number \( n = 0 \). The Lorentz force is given by the formula

\[
F_L = \frac{\Phi_0}{c} J ,
\]

(3.4)
where $J$ is the surface current density in the layer with $n = 0$ at the position of the pointlike vortex, and

$$I = \int_{0}^{\infty} J \, dx \quad .$$

(3.5)

Note that as well as $I$ the value of $J$ is the same in each of the layers.

We use the method of images to find the surface current density $J$. It follows from this method that inside the sample $J$ is a sum of the current densities induced by the pointlike vortices $J_{nk}^{(\infty)}$ and their images (antivortices) $J_{nk}^{(0)}$, i.e.,

$$J = \sum_{n} \sum_{k} \left[ J_{nk}^{(\infty)} + J_{nk}^{(0)} \right] \quad .$$

Combination of Eqs. (3.6) and (3.4) results in the formula determining the value of $J$ as

$$J = \frac{c}{\Phi_{0}} \sum_{n} \sum_{k} \left[ F_{nk}^{(\infty)} + F_{nk}^{(0)} \right] \quad ,$$

(3.7)

where $F_{nk}^{(\infty)}$ is the Lorentz force resulting from the $k$th vortex in the $n$th layer, and $F_{nk}^{(0)}$ is the Lorentz force resulting from the $k$th antivortex in the $n$th layer. Integration of both sides of Eq. (3.7) over $x$ from $x = 0$ to $\infty$ leads to an expression determining the value of $I$:

$$I = \frac{c}{\Phi_{0}} \sum_{n} \sum_{k} \left[ G_{nk}^{(\infty)} + G_{nk}^{(0)} \right] \quad .$$

(3.8)

Here $G_{nk}^{(\infty)}$ is the energy of interaction between the pointlike vortex residing in the layer $n = 0$ at $x = \infty$ and the $k$th pointlike vortex residing in the $n$th layer, and $G_{nk}^{(0)}$ is the energy of interaction between the pointlike vortex residing in the layer $n = 0$ at $x = \infty$ and the $k$th pointlike antivortex residing in the $n$th layer. It is convenient to rewrite Eq. (3.8) in the following way:

$$I = \frac{c}{\Phi_{0}} \left[ G_1 + G_2 \right] \quad ,$$

(3.9)

where

$$G_1 = \sum_{k} \left[ G_{k0}^{(\infty)} + G_{k0}^{(0)} \right] \quad$$

is the energy of interaction with the pointlike vortices and antivortices residing in the layer with $n = 0$, and

$$G_2 = \sum_{n \neq 0} \sum_{k} \left[ G_{nk}^{(\infty)} + G_{nk}^{(0)} \right] \quad$$

(3.10)

(3.11)

is the energy of interaction with the pointlike vortices and antivortices residing in the layers with $n \neq 0$.

We calculate the sums given by Eqs. (3.10) and (3.11) using the following formulas:

$$G_p = -2qd \left[ \frac{\Phi_{0}}{4\pi \lambda} \right]^{2} \ln \left[ \frac{\rho}{\xi} \right], \quad z = 0, \quad \xi << \rho \quad ,$$

(3.12)

$$G_p = -4d^{2} \left[ \frac{\Phi_{0}}{4\pi \lambda} \right]^{2} \exp \left[ \frac{-|z|}{\lambda} \right] \ln \left[ \frac{\rho}{\xi} \right], \quad z \neq 0, \quad \lambda << \rho \ quad .$$

(3.13)

Here $G_p$ is the energy of the interaction of two pointlike vortices when $q = 1$, and $G_p$ is the energy of the interaction of a pointlike vortex and pointlike antivortex when $q = -1$:

$$\rho = \left[ (x_1 - x_2)^2 + (y_1 - y_2)^2 \right]^{1/2}, \quad z = z_1 - z_2 \quad ,$$

(3.14)

$$(x_1, y_1, z_1) \quad \text{and} \quad (x_2, y_2, z_2)$$

are the coordinates of the interacting pointlike vortices (antivortices).

We calculate first the value of $G_1(x)$ for $x_m, \ l \ll x$. According to the method of images for each pointlike vortex with coordinates $(x_m, y_m, z_m)$ there is a pointlike antivortex with coordinates $(-x_m, y_m, z_m)$. Finally, it leads to the following expression for $G_1(x)$:

$$G_1(x) = \left[ \frac{\Phi_{0}}{4\pi \lambda} \right]^{2} d \sum_{k} \frac{x}{(x - x_m)^2 + (y - y_k)^2} .$$

(3.15)

For $x_m, \ l \ll x$, Eq. (3.15) reads

$$G_1(x) = \left[ \frac{\Phi_{0}}{4\pi \lambda} \right]^{2} \frac{x}{\sum_{k} \frac{x}{x^2 + y_k^2}} .$$

(3.16)

In the limit $x \rightarrow \infty$ the main contribution in the sum in Eq. (3.16) comes from the interval, where $k \gg 1$. It allows one to substitute the sum in Eq. (3.16) by the integral. Finally, we obtain the value of $G_1(x)$ in the form

$$G_1 = \left[ \frac{\Phi_{0}}{4\pi \lambda} \right]^{2} \frac{dN_{x}}{x^2 N^2 + (k + N_{x}k_0)^2} \quad .$$

(3.17)

It follows from Eq. (3.17) that $G_1 = G_1(\infty)$ is given by the formula

$$G_1 = \left[ \frac{\Phi_{0}}{4\pi \lambda} \right]^{2} dN_{x} \quad .$$

(3.18)

An analogous calculation for $G_2$ results in

$$G_2 = -\frac{1}{2}G_1 \quad .$$

(3.19)

We now combine Eqs. (2.9), (3.1), (3.9), (3.18), and (3.19) to calculate the magnetization $\delta M$ resulting from the pointlike vortices residing in the sample. Finally, we find

$$\delta M = \frac{\Phi_{0}}{8\pi \lambda} N \ln \left( 1 - \frac{4\pi \lambda^2}{\Phi_{0}} \right) .$$

(3.20)

Note that Eq. (3.20) does not depend on the distribution function $f(u)$. The accuracy of Eq. (3.20) is of the order of $L / L \ll 1$, where $L$ is the characteristic size of the sample in the superconducting layers plane. It means that Eq. (3.20) is an exact formula for any macroscopic sample.

Thus it follows from Eq. (3.20) that in order to find the magnetization relaxation equation we have to know the rate of $N$. To calculate it we treat the diffusion of the pointlike vortices in the stripe $0 < x < x_g$.

**IV. DIFFUSION EQUATION FOR POINTLIKE VORTICES**

We consider here, as an illustration, the magnetization relaxation for the following problem. A semi-infinite lay-
The inequality \( k_B T \ll G_g \) results in zero pointlike vortices density at \( x = x_g \). The solution of Eq. (4.4) matching this boundary condition has the form:

\[
\frac{D n(x)}{dx} \exp \left[ -\frac{G_g(x)}{k_B T} \right] \int_x^\infty \exp \left[ -\frac{G_g(x')}{k_B T} \right] dx' = 0.
\]  

(4.6)

The inequality \( G_m(0) \approx G_m(\xi) \gg k_B T \) allows one to estimate the value of \( n(0) \) as

\[
n(0) = \frac{\gamma_n}{\xi^2} \exp \left[ -\frac{G_g(0)}{k_B T} \right],
\]  

(4.7)

where \( \gamma_n \) is a numerical factor of the order of 1. Using Eq. (4.6) and the boundary condition (4.7) we find the pointlike vortices flow \( j \) and the rate of \( N \) in the form

\[
\frac{dN}{dt} = j = \gamma_j \int \left[ \frac{k_B T}{d} \right]^{1/2} \left[ \frac{4\pi\lambda}{\Phi_0} \right]^2 \frac{M_0}{\tau_0} \exp \left[ -\frac{G_g}{k_B T} \right].
\]  

(4.8)

Here \( \gamma_j \) is a numerical factor of the order of 1, \( M_0 \) is the absolute value of the initial magnetization

\[
M_0 = \frac{1}{4\pi} H,
\]  

(4.9)

and

\[
\tau_0 = \frac{\lambda^2}{\rho_n c^2}
\]  

(4.10)

is the characteristic time constant appearing in the theory of nonequilibrium superconductivity. 22

The combination of Eqs. (3.20) and (4.8) determines the magnetization relaxation due to the thermally activated penetration of the pointlike vortices inside the sample. To find the dependence \( N(t) \) and thus \( dM \), we have to take into account that the interaction of the incoming pointlike vortex with the pointlike vortices residing in the sample results in a shift of the energy barrier \( \delta G_g \). Thus to find the final form of the equation determining the magnetization relaxation we have to calculate \( \delta G_g \) as a function of \( dM \).

**V. ENERGY BARRIER SHIFT FOR POINTLIKE VORTICES**

The interaction of the incoming pointlike vortex with the pointlike vortices residing in the vicinity of the energy minimum at \( x = x_m \) determines the value of \( \delta G_g \). The calculation of \( \delta G_g \) is similar to the calculation of \( \delta M \) (see Sec. III). The interaction of the incoming pointlike vortex with the pointlike vortices and antivortices residing in the same superconducting layer increases the energy barrier by a certain amount \( \delta G_1 \). The interaction of the incoming pointlike vortex with the pointlike vortices and antivortices residing in the superconducting layers above and below decreases the energy barrier by a certain amount \( \delta G_2 \). The total energy barrier shift is equal to

\[
\delta G_g = \delta G_1 + \delta G_2.
\]  

(5.1)
Using Eqs. (3.12) and (3.13) the expression for \( \delta G_1 \) can be written in the form

\[
\delta G_1 = \left[ \frac{\Phi_0}{2\pi \lambda} \right]^2 d \sum_k \frac{x_m x_k}{x_m^2 + (y - y_{k0})^2} .
\]

(5.2)

It follows from Eq. (5.2) that \( \delta G_1 \) is an oscillating function of \( y \). The energy barrier shift \( \delta G_1 \) has a minimum if

\[
|y - y_{k0}| \approx |x_m| \approx \lambda .
\]

(5.3)

The characteristic value of this minimum is of the order of

\[
\delta G_1 \approx \frac{\Phi_0^2 d N^2}{\lambda^2 H}.
\]

(5.4)

Using Eqs. (3.12) and (3.13) the expression for \( \delta G_2 \) can be written in the form

\[
\delta G_2 = -\left[ \frac{\Phi_0}{4\pi \lambda} \right]^2 \frac{d^2}{\lambda} \sum_n \exp \left[ -|n| \frac{d}{\lambda} \right] \times \sum_k \frac{x_m x_k}{x_m^2 + (y - y_{k0})^2} .
\]

(5.5)

The main contribution to the value of \( \delta G_2 \) results from the interaction with the pointlike vortices and antivortices located in different superconducting layers at the coordinates \( (y_{m0}, y_{k0}) \), where \( |y - y_{k0}| < x_m \). It follows from Eq. (5.5) that the total number of sufficient terms in the sum over \( k \) and \( n \) is of the order of \( N x_m \lambda / d \) and the value of \( \delta G_2 \) is equal to

\[
\delta G_2 = -\gamma \frac{\Phi_0}{4\pi \lambda} \frac{N d}{\lambda} .
\]

(5.6)

where \( \gamma \) is a numerical factor of the order of 1. Comparing Eqs. (5.4) and (5.6) we see that the main term in the energy barrier shift \( \delta G_2 \) is determined by \( \delta G_2 \). Using Eq. (3.20) the value of \( \delta G_2 \) can be written as the following function of \( \delta M \):

\[
\delta G_2 = -\gamma \frac{\delta M}{2\pi \lambda} \left[ \frac{\Phi_0}{4\pi \lambda} \right]^2 d \ln^{-1} \left[ \frac{4\pi \lambda^2 H}{\Phi_0} \right] .
\]

(5.7)

VI. MAGNETIZATION RELAXATION

Combining Eqs. (3.20), (4.8), and (5.7) we find the equation determining the magnetization relaxation in the form

\[
\frac{dM}{dt} = \frac{\alpha}{\tau} \exp \left[ -\frac{\delta M}{\alpha M_0} \right] ,
\]

(6.1)

where

\[
\alpha = \gamma \frac{k_B T}{d} \left[ \frac{4\pi \lambda^2 H}{\Phi_0} \right] ,
\]

(6.2)

\[
\tau = \gamma \tau_0 \left[ \frac{k_B T}{d} \right]^{1/2} \exp \left[ \frac{G_2}{k_B T} \right] ,
\]

(6.3)

\( \gamma_a \) and \( \gamma_e \) are numerical factors of the order of 1.

The solution of Eq. (6.1) has the form

\[
M = M_0 \left[ 1 + \alpha \ln \left( \frac{\tau}{\tau - t} \right) \right] .
\]

(6.4)

Thus the thermally activated pointlike vortices penetration into the sample led to a specific initial avalanche-type dependence of the magnetization on time. The characteristic time of the magnetization decay \( \tau \) strongly (exponentially) depends on the energy barrier and the temperature. The dimensionless amplitude \( \alpha \) of the magnetization relaxation is proportional to the temperature and logarithmically depends on the applied magnetic field.

The dependence given by Eq. (6.4) is valid until

\[
\delta M = \alpha M_0 \ln \left( \frac{\tau}{\tau - t} \right) < M_0 ,
\]

(6.5)

and the density of vortices \( N \) is less than a certain critical value \( N_c \approx 10^3 \). When \( N \) becomes of the order of \( N_c \) the Abrikosov vortices self-assemble from the pointlike vortices and then penetrate inside the bulk. It follows from Eqs. (3.20) and (6.4) that a noticeable increase of \( N \) starts when \( t \approx \tau \).

The penetration of the Abrikosov vortices inside the bulk changes the time dependence of the magnetization decay to the regular logarithmic law. The latter leads to the magnetization relaxation rate decreasing in time. Thus at \( t \approx \tau \) the magnetization relaxation rate has a maximum.

To estimate the values of the characteristic time constant \( \tau \) and the dimensionless amplitude of the magnetization relaxation \( \alpha \) we use \( \gamma_a = \gamma_e = 1 \) and the data obtained for a monocrystal Bi_Sr_2CaCu_2O_8, \( \lambda \approx 3 \times 10^{-5} \) cm, \( \xi \approx 6 \times 10^{-7} \) cm, \( d \approx 1.5 \times 10^{-7} \) cm, \( \rho_n \approx 10^{-5} \) \( \Omega \) cm. Using Eqs. (2.6), (6.2), and (6.3) we find that if \( T \ll T_c \) and \( H \geq H_c = 0.13 \) T, then

\[
\tau \approx 10^{-13} \left[ \frac{T}{300} \right]^{1/2} \exp \left[ \frac{300}{T} \ln \left( \frac{0.7}{H} \right) \right] ,
\]

(6.6)

\[
\alpha \approx \frac{T}{300} \ln(500H) ,
\]

(6.7)

where the temperature \( T \) is given in K and the magnetic field \( H \) is given in T. Substituting in Eqs. (6.6) and (6.7), \( T = 25 \) K and \( H = 0.04 \) T, we find \( \tau \approx 30 \) s and \( \alpha \approx 0.25 \). These numbers seem to be reasonable for the experimental observation of the main peculiarities of the magnetization relaxation due to the thermally activated penetration of the pointlike vortices.

VII. SUMMARY

To summarize, we have shown that in an external magnetic field higher than \( H_0 \) the energy of a pointlike vortex \( G_0 \) has a minimum \( G_{m} \) detached from the sample surface by an energy barrier \( G_{s} \). The value of \( G_{m} \) becomes negative in magnetic field higher than \( H_1 \approx H_{c1} \). We have calculated the time dependence of the magnetization rela-
tion due to the thermally activated penetration of point-like vortices inside the sample. We have shown that this process results in an avalanche-type initial decay of the magnetization and a specific maximum in the magnetization relaxation rate at a certain moment of time $t \approx \tau$. The value of $\tau$ exponentially depends on the ratio of the energy barrier $G_\phi$ and $k_B T$.
